Abstract—There are strong needs for both mobile and temporal properties in process algebras designed to specify and analyze distributed mobile real-time systems (DMRS). However there is no practical process algebra with both properties. For example, there is no mobile property in TCCS with the temporal, and, similarly, there is limited temporal property in d-Calculus with the mobile. In order to solve these limitations, this paper proposes dT-Calculus with expressive power of movements of processes with temporal condition. dT-Calculus extended the basic temporal properties of synchronous process movement of d-Calculus into more specific temporal properties in order to specify and analyze the temporal property of DMRS more effectively: ready time, execution time, waiting time, deadline, etc. In order to simulate the proposed process movement with temporal properties, the SAVE tool has been developed on ADÖxx Meta-Modeling Platform and demonstrates efficiency and effectiveness of the proposed approach with an EMS example.

Keywords—dT-calculus; d-calculus; Process Algebra; Mobility; Time; SAVE

1 INTRODUCTION

There are a number of process algebras to specify and analyze the requirements of distributed mobile real-time systems (DMRS). Different from other systems, DMRS requires both mobile and temporal requirements to be specified and analyzed [1]: Mobility allows various types of inter-process relations to be specified and analyzed; Temporalnness does allows the temporal conditions for the inter-process relations to be specified and analyzed. However there were limitations in the existing process algebras to represent both mobile and temporal properties together at the same specification and analysis. This paper proposes a new process algebra, called dT-Calculus, which can express effectively both mobile and temporal properties of processes in DMRS, in order to specify and analyze the mobile and temporal requirements of DMRS.

Among the existing process algebras, Timed pi-Calculus [2] and d-Calculus[3] can be classified as the ones that can represent both mobile and temporal properties of DMRS. The main characteristics of the properties can be summarized as follows:

1) Timed pi-Calculus: The existing pi-Calculus [4] expresses process movements indirectly by using the notion of value passing. Timed pi-Calculus is the timed version of pi-Calculus, which allows time-stamp and clock be passed additionally during value passing: the temporal requirements of the process movements can be specified.

2) d-Calculus: This is a process algebra that can express direct process movements into or out of other processes by using the 4 types of synchronous movements with simple temporal conditions: a bound of the minimum and maximum limits. It naturally allows process nesting by the resulting inclusion relations among processes.

The above algebras are designed to specify the mobile and temporal requirements of process movements, but there are some limitations to specify the requirements fully, considering different temporal properties of the requirements:

1) Timed pi-Calculus: It allows various types of temporal requirements to be specified, but the actual execution time of action itself and types of movements are not possible to specify in the requirements.

2) d-Calculus: It allows various types of temporal requirements to be specified, but only simple type of temporal requirements for process movements is possible. For example, a temporal bound of the minimum and maximum limits. It results in limited specification of the temporal requirements of the movements as well as analysis of the requirements.

In order to overcome these limitations, this paper proposes a process algebra, namely, dT-Calculus, which...
is the timed version of d-Calculus, extended for more specific temporal specification and analysis of the requirements. dT-Calculus allows the temporal properties of the actions of the DMRS processes to be expressed as follows:

- **Ready time**: The time needed before execution of action.
- **Timeout**: The maximum waiting time up to the actual execution of action is possible, after the execution of the action is ready with the ready time.
- **Execution Time**: The actual execution time of an action or a process.
- **Deadline**: The time that the execution of action is to be terminated.
- **Period**: Periodic repetition of an action or a process.

These specific temporal properties allow various types of temporal requirements of process movements over the DMRS environment to be specified and analyzed, without modifying any types of the process movements from d-Calculus.

This paper is organized as follows. Section II introduces some of the existing process algebras with temporal properties. Section III introduces the basic algebra for dT-Calculus, that is, d- Calculus. Section VI describes syntax and semantics of dT-Calculus, focusing on its temporal properties. Section V demonstrates usability of dT-Calculus with a simple example. Section VI shows some comparison dT-Calculus with other process algebras. Section VII introduces a tool, called SAVE, which is developed, on ADOxx Meta-Modeling Platform, to specify and analyze the temporal requirements of the process movements with dT-Calculus. Finally conclusions will be made and some of future researches will be discussed.

### 2 RELATED RESEARCH

One of the best known process algebra to specify and analyze the temporal property is *Timed pi-Calculus*. It is an timed version of pi-Calculus designed of Milner [4], adding the temporal property for process movements. Fig. 1 shows the syntax of Timed pi-Calculus.

In the *send* and *receive* actions, \( t \) and \( c \) represent *time-stamp* and *clock* used for creating of the time-stamp, respectively. Further \( \delta \) and \( \gamma \) represent *temporal restriction condition* and *clock reset*, respectively. The process specification with temporal restriction condition is to be used as follows:

\[
P = (c < 2)\bar{x}(y,t_c,c).P'
\]

It implies that, in 2 time units after *clock c* is reset, *name y* can be transmitted through *channel x* in \( t_c \).

The notion of clock in Timed pi-Calculus is based on local clock concept, which allows various kinds of temporal restriction conditions. For example,

\[
Q = (e > 5)(d-t_c \leq 3)x((z,t_c,d))Q'
\]

It specifies two temporal conditions with clock: \((e > 5)\) represents a condition for a local clock \( e \), and \((d-t_c \leq 3)\) represents a temporal condition related to a receiving message. \( d \) and \( t_c \) are times on the clock for the receiving message and its time-stamp, but, since the clock ticks continuously, \((d-t_c \leq 3)\) implies the temporal condition that the message should be transmitted in 3 time units.

The mobile property of Timed pi-Calculus is represented indirectly by changing the state of channel connection among processes through passing the connecting channel names. For example,

\[
\bar{y}x.P'|y(z).Q'|R \rightarrow P'|Q'[x/z]|R
\]

As shown in Fig. 2, it represents the state of \( P \) and \( R \), connected by \( x \), to be changed to the state of \( Q \) and \( R \), newly connected by \( x \), after passing the name \( x \) to \( Q \) by \( P \) through the channel \( y \). Obviously the connection between \( P \) and \( R \) is invalid since there is no \( x \) in \( P \).

3 PREVIOUS RESEARCH

d-Calculus is the process algebra developed to specify and analyze the process movements directly on geographical space. There are four types of movements in d-Calculus and all of them are synchronously defined.

![Figure 3 Syntax of d-Calculus]

3.1 Syntax

The syntax of d-Calculus is shown in Fig. 3 and is defined as follows:

1) Action: Actions performed by a process.
2) Priority: The priority of the process $P$ represented by a natural number $n \geq 0$. The higher number represents the higher priority. Exceptionally, 0 represents the highest priority.
3) Nesting: $P$ contains $Q$. The internal process is controlled by its external process. If the internal process has a higher priority than that of its external, it can move out of its external without the permission of the external.
4) Channel: A channel $r$ of $P$ to communicate with other processes. $t$ implies the time needed for the communication through the channel.
5) Choice: Only one of $P$ and $Q$ will be selected nondeterministically for execution.
6) Parallel: Both $P$ and $Q$ are running concurrently.
7) Exception: Execution of $P$, but $F$ in case of violation of the deadline $t$.
8) Sequence: $P$ follows after action $A$.
9) Empty: No action.
10) Send/Receive: Communication between processes, exchanging a message by a channel $r$. $t$ represents deadline of the communication.

11) Request: Requests for movement. $t$, $p$ and $k$ represent deadline, priority and key, respectively.
12) Permission: Permissions for movement. $t$ represents deadline.
13) Create process: Creation of a new internal process. The new process cannot have a higher priority than its creator.
14) Kill process: Termination of other processes. The terminator should have the higher priority than that of the terminatee.
15) Exit process: Termination of its own process. All internal processes will be terminated at the same time.

Generally all the movements are synchronous. In order for a process to move in or out of another process, the moving process (mover) needs a permission from the target process. Reversely, in order for a process to be moved in or out of another process forcefully, the moving process needs a permission from the being-moved process (movee).

By means of the strict method of synchrony, the movements of processes can be controlled, and further the security and safety of DMRS can be guaranteed by pre-cautiously preventing insecure or unsafe movements.

![Figure 4 Pictorial View of d-Calculus Movements]

3.2 Mobility

As stated, the process movement in d-Calculus occurs synchronously between the requesting process and the permission process. It implies that the movement cannot be allowed without the permission. It prevents any unplanned movement from occurring unexpectedly, and clarifies control of the movement explicitly. There are four types of such movements in d-Calculus as follows:

- in: A process moves into another process directly.
- out: A process moves out of another process directly.
- get: A process makes another process move into itself.
• put: A process makes another process move out of itself.

The types of movements can be pictorially depicted as shown in Fig. 4.

4 dT-Calculus

dT-Calculus is the process algebra developed to specify and analyze the process movements of DMRS with temporal restrictions directly on geographical space. In order to represent precise temporal properties explicitly, it extended the basic temporal property of the movements in d-Calculus to the different types of temporal properties for period and sporadic actions or processes, with the additional syntax and semantics accordingly.

4.1 Time Properties

There are five temporal properties in dT-Calculus: ready time, timeout, execution time, deadline, and period. The first 4 properties are used to specify the temporal properties of sporadic actions or processes, and the last one is used to specify the temporal properties of periodic actions and processes inclusively. The definition of each property is as follows:

1) Ready time: It represents the waiting time for an action. At the point of the action in a process, the process was to wait for ready time before executing the action. No other or synchronous action are possible during ready time.

2) Timeout: It represents the maximum waiting time for the actual execution of an action to be started after the action is ready for execution. If the waiting time in ready time is over and the partner for its synchronous action is not ready, the action cannot be executed. If the partner is ready for the action in timeout, the action can be executed. If not, the action will be in the state of timeout, the process will be in some fault state unless some proper handling action is not specified.

3) Execution Time: The time needed to execute an action. In case that the action can be performed in timeout after ready time, the action will be executed in execution time and be terminated. And then the next action will be available.

4) Deadline: The termination time for the execution of an action. All actions must be terminated in deadline. Deadline starts as ready time does. If the action is terminated in deadline, the process will be in some fault state. In order to prevent the process from being in the fault state, an exceptional handling must be specified accordingly.

5) Period: The duration of period for the execution of an action or process in repetition. The action will repeat itself after period of executing the action or process. This is an additional temporal property to specify the periodic action or process, different from the previous four temporal properties. The periodic action or process can be put into some fault state due to failure to timeout and deadline.

All actions and processes are defined or specified with these temporal properties. However the properties cannot be applied to some actions and processes. For example, empty action, no-time action, timed process, etc.

Fig. 5 Syntax of dT-Calculus

4.2 Syntax

The syntax of dT-Calculus is shown in Fig. 5, and the extended notions from d-Calculus for temporalness are as follows:

1) Timed action: The execution of an action with temporal restrictions. The temporal properties of \([r, t, o, e, d]\) represent ready time, timeout, execution time, and deadline, respectively. \(p\) and \(n\) are properties for periodic action or processes: \(p\) for period and \(n\) for the number of repetition.

2) Timed process: Process with temporal properties.

3) Exception: \(P\) will be executed. But \(F\) will be executed in case that \(P\) is out of timeout or deadline.

The biggest difference of dT-Calculus with d-Calculus is the notion of timed action and processes. In d-Calculus, the temporal property is simple defined with \(t\) in action or process: the boundary of the lower and upper
time limits. However, in dT-Calculus, the property is divided into more specific properties, as described. In addition, the exceptions caused by the violation of the temporal properties are more specifically divided into the one by \textit{deadline} and the one by \textit{timeout}.

Consequently the separate notions for temporal properties for action and process in d-Calculus can be represented in one single notion and form of the properties in dT-Calculus.

If there is no temporal properties to be specified in an action, it will be considered to be $[0,\infty,1,-]$, by default. That is, there is no waiting time so that the action can be executed immediately, and infinite waiting for the synchronous co-action is possible without \textit{timeout} and \textit{deadline}.

### 4.3 Semantics

The semantics of dT-Calculus for the temporal properties in action and process are defined as transition rules as show in Table 1.

<table>
<thead>
<tr>
<th>Rule</th>
<th>Transition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tick-Time R</td>
<td>$A(r,0,n,d) \xrightarrow{-e_1} A(r,0,n,d-1)$ ($r \geq 1$)</td>
</tr>
<tr>
<td>Tick-Time TO</td>
<td>$A(0,0,n,d) \xrightarrow{-e_2} A(0,0,n-1,d-1)$ ($n \geq 1$)</td>
</tr>
<tr>
<td>Tick-Time End</td>
<td>$A(0,0,0,d) \xrightarrow{-} A'$</td>
</tr>
<tr>
<td>Tick-Time SyncE</td>
<td>$A'[0,m,n,d] \xrightarrow{(r+e_1+e_2)} A''[0,m,n-1,d-1] (e_1 \geq 1 \land e_2 \geq 1)$</td>

<td>$A'[r,m,n,d] \xrightarrow{-e_6} A'[r,m,n-1,d] (n &gt; 1)$</td>
</tr>
<tr>
<td>Period End</td>
<td>$A'[r,m,n,d] \xrightarrow{-e_7} A'$</td>
</tr>
</tbody>
</table>

\textbf{Table 1 Temporal Semantics of dT-Calculus}

Each rules in the table are defined as follows:

1) Tick-Time R: The rule for \textit{ready time} of an action. As time passes in \textit{ready time}, the values of $r$ and $d$ decrease accordingly.
2) Tick-Time TO: The rule for timeout of an action. The action, not executing, but in waiting, decreases its \textit{timeout} time accordingly as time passes.
3) Tick-Time End: The rule for termination of an action. After the execution of the action started and the value of $e$ becomes 0, the next action can start.
4) Tick-Time SyncE: The rule for execution of an action. When an action and its partner co-action are executed synchronously, the values of $e$ and $d$ decrease accordingly as time passes.
5) Tick-Time AsyncE: The rule for execution time of an asynchronous action. In case of asynchronous action, there is no need for \textit{timeout}: it goes into its own execution immediately just after \textit{ready time}; the values of $e$ and $d$ decrease accordingly as time passes.
6) Tick-Time P: The rule for passage of time in process. Since the temporal property for a process uses only deadline in its temporal requirements, the value of $e$ decreases accordingly as time passes.
7) Timeout: The rule for \textit{timeout} to occur. When the values of $e$ and $d$ becomes 0, its \textit{timeout} error will occur. However, when an exception for the \textit{timeout} defines, its exception handling will be activated accordingly.
8) Deadline: The rule for violation of \textit{deadline}. When the value of $d$ becomes 0, its \textit{deadline} error will occur. However, when an exception for the \textit{deadline} defines, its exception handling will be activated accordingly.
9) Period: The rule for execution of a periodic action. The action will be executed again after the period passes, and the value of $n$ will be decremented by 1.
10) Period End: The rule for termination of a periodic action. In case that the value of $n$ is 1, no action will be repeated after the period passed over.

### 4.4 Laws

The laws for the additional temporal properties in dT-Calculus are shown in Table 2. The laws represent the notion and restrictions of temporal properties in dT-Calculus as follows:

1) Timed Process: Only applicable temporal property for a process is \textit{deadline}. 

---

ISSN: 2367-8895 57 Volume 2, 2017
2) Non-time Action: The action with no temporal properties is same as the one with the temporal properties of \([0,-,1,-]\).

3) Empty: Only applicable temporal property for the Empty action is execution time.

| \(P_{[r,u,d,e]} = P_{[-,\cdot,-,\cdot]}\) | Timed Process |
| \(A = A_{[0,-,1,-]}\) | Non-time Action |
| \(\emptyset_{[r,u,d,e]} = \emptyset_{[-,\cdot,-,\cdot]}\) | Empty |

Table 2 Temporal Laws of dT-Calculus

4.5 Characteristics

The temporal properties are directly specified to each action and process in dT-Calculus. The specification of the temporal specification of both actions and processes allows the temporal requirements for both actions in a processes and the process itself to be specified and analyzed at the same time.

The introduction of the periodic temporal property has many advantages than other process algebras in specification of different types of repeating processes. Generally, the starting time of each synchronous action depends on the ready time of its partner action so that the same actions may require different total execution or termination time of their synchronous actions. That is, there is some problem of not being able to specify explicitly and precisely the temporal properties of periodic actions in the following form:

\[ A \cdot \emptyset_{[-,\cdot,-,\cdot]} \cdot A \cdot \emptyset_{[-,\cdot,-,\cdot]} \cdot A \cdot \emptyset_{[-,\cdot,-,\cdot]} \cdot \ldots \]

It was intended to specify the above periodic actions with empty actions, but the empty actions with fixed execution time were not appropriate because their interaction times for synchronization can be different from each other. However, there is an advantage that there is no need to consider such time for synchronous interactions if the periodic temporal property is used. The specification of the periodic requirements becomes very simple since the next execution of an action will be performed after elapsing the periodic temporal duration without calculating the temporal length left over up to the next re-execution of the action after the immediate execution of the action.

5 Example

This section describes the specification of analysis of DMRS in dT-Calculus with an Emergency Medical Systems (EMS) example.

EMS is the system where, in case of traffic and automotive accidents, the drivers of the automotive or patients from the accidents are transported to proper medical institutes under control of the 911 systems contacted by the driver or patients, or some smart devices of them.

5.1 Specification

As shown in Fig. 6 in dT-Calculus, the EMS in the example operates as follows:

1) At the time of an car accident, the driver of the car acknowledges the accident.
2) The driver attempts to move out of the car.
3) If the driver does, he/she calls 911 and informs of the accident. If not, the smart device connected with the smart car acknowledges the situation and sends an emergency signal to 911 of the accident.
4) At the call, either from the driver or the device, 911 selects appropriate ambulance from 911 for proper treatment.
5) Once the ambulance arrives at the scene of the accident, the medic takes the driver or patient on the ambulance.
6) The ambulance performs the first treatment on the driver or patient and transports him/her to the near hospital.
7) After arriving the hospital, the ambulance takes the driver or patient off at the hospital and informs 911 of accomplishment of the transportation.
8) The driver or patient is being treated in the hospital.

\[ EMS ::= Car[Drv] \mid 911[Amb1[-,\cdot,-,40]] \mid Amb2[-,\cdot,-,40] \mid Hsp; \]
\[ Car ::= CD(crash) \cdot Drv\out{[0,5,1,7]} \cdot (CE(call)) \cdot AC(open) \cdot put Drv; \]
\[ Drv ::= CD(crash) \cdot (out Car \cdot DE[call] + \emptyset_{[-,7,-,10,-]} \cdot Car put) \cdot ((Amb1 get \cdot AD(em) \cdot Amb1 put) + (Amb2 get \cdot AD(em) \cdot Amb2 put)) \cdot HD(tr); \]
\[ 911 ::= (DE[call][0,5,1,7]) \cdot ((EA1(Lv1) \cdot Amb1 out) + EA2(Lv1))) \cdot (CE[call] \cdot (EA(Lv2) \cdot amb1 out) + EA2(Lv2))) \cdot EA(done); \]
\[ Amb1 ::= \left( EA1(Lv1)[0,5,1,7] \cdot (out 911)[0,5,-1] \right) \cdot (EA1(Lv2) \cdot (out 911)[0,5,-1] \cdot AC(open)) \cdot get Drv \cdot AD(open) \cdot (in Hsp)[0,10,-] \cdot put Drv \cdot EA(done); \]
\[ Amb2 ::= \left( EA2(Lv1)[0,5,1,7] \cdot \emptyset_{[-,3,-]} \right) \cdot (EA2(Lv2) \cdot \emptyset_{[-,3,-]} \cdot AC(open)[0,7,-]) \cdot get Drv \cdot AD(open) \cdot (in Hsp)[0,10,-] \cdot put Drv \cdot EA(done); \]
\[ Hsp ::= (Amb1 in + Amb2 in) \cdot HD(tr); \]

Fig. 6 EMS Example in dT-Calculus
Fig. 6 shows the EMS example in dT-Calculus, specified based on the above operations. In the specified, the following action has been declared in the Car process to detect the case of the driver not moving out of the car autonomously:

\[ \text{Car} := ... \text{Drv out}_{[0,5,1,7]} \setminus (CE(cali))... \]

It implies that, if the action is not completed in the 5 time units of \([0,5,1,7]\), the car is to call 911 automatically by means of exceptional handling of the case. In the specification of Fig. 6, the call from the car, \(CE(cali)\), always occurs after the call from the driver, \(DE(cali)\), by the operations. Therefore, the calls from the car and driver are designed to handle separately in the Amb1 and Amb2 processes by setting the timeout for receiving the calls in the process.

Amb1 in 911 and Amb2 out of 911 have different characteristics. Amb2 arrives at the scene earlier, it takes more time to open the doors of the car. Therefore, depending on the status of the patient, the transportation times by Amb1 and Amb2 are different.

5.2 Graphical representation

The textual specification in dT-Calculus can be represented graphically in two views: in-the-large (ITL) and in-the-small (ITS). The ITL view can be considered as System View consisting of processes interacting together with communication and movements. The ITL view can be considered as Process View with the detailed actions. Fig. 7 and 8 show the ILT and ITS views of the EMS example, respectively.

5.3 Execution

As shown in Fig. 9, there are total 16 paths: 4 normal execution paths and 12 abnormal paths. The abnormal ones are due to improper selection of the branches at the choice statements. For example, it is the case that 911 sent a signal to Amb1 and moved to the scene, but the patient waits for Amb2.

For the normal execution paths, it is possible to perform analysis of their temporal properties.

Firstly, the case that the patient moves out of the car safely first is as follows:

1) T1: An accident occurs and the driver moves out of the car safely by himself or herself.
2) T2: The driver moves out of the car.
3) T3: The driver calls 911.
4) T4: 911 calls its ambulance to go to the place where the accident occurred.

Here the time to arrive at the scene by the ambulance is different, depending on which ambulance is chosen to handle the situation by 911. Therefore, the time that the ambulance arrives at the scene is defined as \(t\):
5) T4+t: The ambulance moves out of 911 and arrives at the place.
6) T5+t: The driver hops on the ambulance.
7) T6+t: The medic in Ambulance performs the first aid treatment for the driver.
8) T16+t: The ambulance arrives at a hospital.
9) T17+t: The medic helps the driver to move into the hospital.
10) T18+t: A doctor in the hospital treats the driver and the ambulance sends 911 a message of completing its mission.

Amb1 consumes total 23 unit times, since $t=5$; Amb2 does total 21 unit time, since $t=3$.

Secondly, the case that the patient does not move out of the car safely is as follows:

1) T1: An accident occurs and the driver is unconscious.
2) T6: The car acknowledges that the driver cannot move out of the car after the accident.
3) T7: The car sends 911 a message of the accident.
4) T8: 911 calls its ambulance to go to the place where the accident occurred.

Similar to the first case, here the time to arrive at the scene by the ambulance is different, depending on which ambulance is chosen to handle the situation by 911. The time that the ambulance arrives at the scene is defined as $t$.

5) T8+t: The ambulance moves out of 911 and arrives at the place.

Here the time to open the doors of the car is difference. Therefore the time is defined as $d$.

6) T8+d: The medic opens the driver-side door of the car.
7) T9+d: The medic moves the driver out of the car.
8) T10+d: The medic moves the driver into the ambulance.
9) T11+d: The medic performs the first aid treatment for the driver.
10) T21+d: The ambulance arrives at a hospital.
11) T22+d: The medic moves the driver into the hospital.
12) T23+d: A doctor in the hospital treats the driver and the ambulance sends 911 a message of completing its mission.

For Amb1, $t=5$, $d=1$; for Amb2 $t=3$, $d=7$. Therefore Amb1 consumes 29 unit times; Amb2 consumes 33 unit times.

As the results of the execution, it is known that the deadline for the Amb1 and Amb2 processes is satisfied. In addition, it is possible to determine which ambulance to send for treatment depending on the status of the patient. In case that the patient moves out of the car autonomously, Amb2 is better since it arrives earlier than Amb1. However, in case that the patient is not able to do so, Amb1 is better since it opens the doors faster even though it arrives little late.

6 Comparative Analysis

Timed pi-Calculus is a process algebra that is designed to specify and analyze smart mobile services. Timed pi-Calculus is the timed version of pi-Calculus, which allows time-stamp and clock be passed additionally during value passing: the temporal requirements of the process movements can be specified. However there is a limitation that the execution time of an action cannot be specified directly on the action. Further it is difficult to analyze the execution time, the deadline, and others of an action, since such temporal properties are represented by the passing time-stamp and clock. Similarly the movement in the algebra is inappropriate to represent a real movement of a process since it is represented by value passing. Consequently such indirect representation of a movement may result in
distortion of the patterns of real movements since the representation reduces the scope of the possible movements in expression.

\textit{d-Calculus} is a process algebra that is designed to express direct process movements into or out of other processes both autonomously and heteronomously. It allows various types of mobile requirements to be specified, but only simple type of temporal requirements for process movements is possible: A temporal bound of the minimum and maximum limits. It results in limited specification of the temporal requirements of the movements as well as analysis of the requirements. In addition, specification can be represented in both text and graph in order to increase visibility of the specification as well as comprehensibility. However, there are limitations in specification of temporal properties: The execution time is only possible for an action; Deadline is specified only by exception. It implies that only simple temporal specification is possible, but complex temporal specification for the smart EMS example is not possible.

However, \textit{dT-Calculus} overcomes these limitations of these algebras. Since it is an extension version of \textit{d-Calculus}, it can utilize all different types of direct movements of processes. Besides, it is possible to specify complex temporal requirements of the smart mobile service by supplying a variety of additional temporal properties. Further, the analysis of the temporal properties is relatively easy since the properties are directly specified on actions and processes. And it is possible to specify exceptional handling to solve errors or faults caused by any violation of timeout and deadline.

7 SAVE

In order to demonstrate the feasibility of the approach in the paper, a tool, called SAVE (Specification, Analysis, Verification and Evaluation), has been developed on the ADOxx Meta-Modeling Platform. There are three basic models defined in SAVE: Specification, Execution and Simulation.

The first step to use SAVE for analysis is to specify systems in \textit{dT-Calculus}. There are two specification models in SAVE, as shown in Fig. 10 and 11 for the EMS example: ITL (In-The-Large) and ITS (In-The-Small). From specification, the execution model can be automatically generated by the execution model generator. The execution model reveals all possible execution paths and determines whether each path is of normal or deadlock. Fig. 12 shows the execution model for the EMS example.

After generating an execution model, the simulation model for each execution path is automatically generated. The simulation model is represented in GTS (Geo-Temporal Space), where all the execution and movements resulted in the path are described in the model in detail. Based on the simulation model, it is possible to analyze and verify the temporal requirements of DMRS. Fig. 13 shows the simulation model for the first path of the EMS example in Fig. 11.
8 CONCLUSION AND FUTURE RESEARCH

This paper proposed a process algebra, called dT-Calculus, for mobile and temporal specification and analysis of Distributed Mobile Real-time Systems. The algebra extended d-Calculus for specification and analysis of a variety of different types of temporal properties at the direct movement actions and the mobile processes. Further a tool, called SAVE, has been developed to demonstrate the feasibility of the approach with the algebra.

Presently in the paper, the process algebra for specification and analysis is proposed. In the future research, the different types of verification methods are developed to demonstrate the usability of dT-Calculus, including SAVE with a verification model.
