Abstract: In this work the data, obtained for the three vehicles (sedan, SUV and Pick Up), tested in previous works, are compared. Following the results found in the literature, particular emphasis is done on the speed of the teenager cyclist head at the instant of impact and the diagrams of the head speed and the chest obtained in the simulations are shown. The speed of the head is that absolute, and this is used for processing the data and the subsequent determination of the best values of the three geometric actual parameters identified in front of the vehicle. Absolute speed is preferred because using the relative speed respect to vehicle, some amounts that cannot be disregarded are omitted from the evaluation. The chosen speed is 30 km/h because higher values appear too dependent on the mass of the vehicle, while lower values may not result in serious injury and are therefore less attractive. The procedure, to obtain the optimal values of the height of the bumper, the height of the bonnet and of the inclination angle of the bonnet is illustrated in the case the side impact vehicle-teenager cyclist. The conclusion is made that analogous procedure can be applied to HIC values.

Key-Words: teenage bicyclist, vehicle impact, bumper height, bonnet height, bonnet angle

1 Introduction

Many works are found in literature on the impact between vehicle and teenager [1] [4] or adult pedestrian [2] [3] [5] [10] [18] [23] [28] [29], also numerous works study the impact between the vehicle and the adult cyclist [9] [11] [13] [16] [17] [20] [21] or both cyclist and pedestrian [6] [7] [8] [12] [22], but the papers on the accident vehicle - teenage cyclist; are not numerous in literature [14] [15] [19] [35] [36] [37]. In [21] Authors indicate that car-mounted countermeasures designed to mitigate pedestrian injury have the potential to be effective even for bicyclists.

In general multibody technique is the applied method for numerical simulation; the most widely used programs are MADYMO, Aprosys, PC Crash, while Sim Wise is effectively used in this paper. Studies give an idea of the shape of the front of the vehicle in order to reduce injuries, that may arise due to the impact [18] [29], but these works are not frequent in literature. In particular the works [21] [22] [23] also address the crash between SUV vehicle against cyclist or pedestrian, but other papers on Pick up – cyclist impact are not found, over the paper [42]. This extends the results already achieved in the papers [14] [15] [37] where the damages caused by the energy impact of a teenage cyclist with a sedan car are taken into account and analyzed. Analogous crash is studied in case of vehicle constituted by a SUV [35] [36] instead than a normal sedan, in order to fill the gap in literature: references are found only to an adult or to a child, in many cases without taking into account the type of vehicle.

The influence of the front of the vehicle on the injury of the cyclist or pedestrian is a topic that is not frequently found in the literature. In [33], [34] Authors investigate the deploying time (or response time) of an active hood lift system (AHLS) of a passenger vehicle activated by gunpowder actuator,
while in [38] four vehicle types including large and compact passenger cars, minivans and light trucks are simulated according to their frequency of involvement in real world accidents. The influences of various vehicle front shape and compliance parameters are analysed. Moreover, the possible countermeasures on basis of vehicle front design to mitigate the injury severity of the pedestrians were discussed. A campaign of virtual simulations is conducted with the availability of the virtual models: sedan [14], SUV [35] and Pick Up [42] teenage cyclist, in order to quantify the damage caused to the head and chest on the basis of certain criteria such as HIC and 3 ms criterion [24] [25]. The results of the head speed of the previous executed simulations are analysed in order to quantify the influence of the front part of the vehicle on the injury of the cyclist head.

2 Implementation of Virtual Models

The paper [1] is very useful for the study of anthropomorphic model of the human figure of a teenager, understood as a complex of bones, muscles and joints, while the paper [3] has analogous value for the adult; the book [26] and the paper [27] are very useful for the chassis design and the geometry of the bike (fig. 1). The implementation of the virtual model of the bike is the same for SUV, Pick up and sedan simulations [14] [35] [36]. Virtual simulations, performed with Sim Wise, allowed quantifying the damages in the teenager cyclist – Pick Up impact on head and chest.

3 Vehicle- cyclist crash test

This paragraph illustrates, through the use of charts, tables and representations, the tests to assess the damage produced on teenage cyclist under varying condition of impact, in order to calculate the speed of the head and the chest for the evaluation of injuries. Dynamic of impact of teenage cyclist – vehicle is reconstructed by Sim Wise. The relative positions between the vehicle and the cyclist are the same as those used for already examined vehicles [14] [15] [35] [36] [37]. The positions are three: In the first the teenage cyclist is positioned on the roadway with the side facing the vehicle about to occur (side impact); in the second case the cyclist is located opposite the vehicle about to occur (frontal impact), while in the third and last case the cyclist is placed behind the vehicle (telescoping or rear impact). Crash tests are executed at four different speeds: 20 km/h, 30 km/h, 40 km/h and 50 km/h. The parameters measured during the tests are:
- Acceleration in the head gravity centre;
- ...
Figure 3: Head and chest acceleration in the side impact at 40 km/h

Fig. 7 - Thorax and head speed in the frontal impact with PICK UP at 40 km/h

Fig. 8 - Thorax and head speed in the side impact with sedan at 30 km/h

Fig. 9 - Thorax and head speed in the side impact with sedan at 40 km/h

Fig. 10 - Thorax and head speed in the side impact with SUV at 20 km/h
3.1 Head impact speed

The parameters measured in the simulations are:
- resulting speed of the head gravity center;
- resulting speed in the thorax gravity center.

Fig. 4 – 14 show the trend of the head and thorax speed versus the time for many executed simulations.

Table 1 shows the obtained results with the values of the maximum impact speed of the thorax and of the head, with the contact time.

Figures 15, 16 and 17 show the trend and the visual comparison.

Fig. 15: maximum head speed in the frontal impact.

These three figures show that the sedan gives the best performance under all conditions of impact compared to other vehicles. This may depend on the gentler shaping of the front; exception to the low speed collision in which the speed of impact of the head take on greater values than other vehicles. In general the resulting speed of the head of the cyclist is greater if the vehicle has high front.
Table 1: max impact speed of the thorax and of the head and the contact time.

In [38] several simulations of vehicle – pedestrian crash are executed by the multibody program MADYMO; in it a simulation technique is applied giving the relative velocity of the head impact speed, while the absolute values are obtained by the technique adopted in this work, so that no numerical or qualitative comparison can be executed.

The reason is basically the following: indicating with \( m_1 \) the mass of the vehicle and \( m_2 \) the mass of the rider (or pedestrian), an instant before the impact, if the speed of the cyclist is neglected, the momentum of the system is given by \( m_1 v_1 \). The two bodies begin to move with speed \( v_2 \) due to the initially inelastic impact, so that the conservation of momentum states:

\[
 m_1 v_1 = (m_1 + m_2) v_2. \tag{1}
\]

Since \( m_1 \) is very greater than \( m_2 \), the solution \( v_2 = v_1 \) is fairly reliable, so that after the impact instant the rider has a relative speed very close to the absolute speed of the vehicle. The speed \( v_2 \) is actually a few less than the speed \( v_1 \), because during the impact phase, which endures small milliseconds, strong impulsive forces are awakened, then strong accelerations vary the kinematic behavior of the vehicle-cyclist system. These accelerations are strongly dependent on the vehicle mass and are in part neglected by examining the relative motion. Looking directly at the relative speeds, the influence of the mass of the vehicle is completely eliminated, but this may modify the dynamic behavior of the system.

4. Best values evaluation and discussion

Table 2 shows the geometric characteristic of the examined vehicles; fig. 18 shows the geometrical position. In the last row of the table the reported

Fig. 16: maximum head speed in the side impact.

best values are calculated by the method described in the following.

Figures 15, 16 and 17 allow the following considerations:
- The impact speed of the head of the teenage cyclist increases varying the considered vehicle.
- The mass of the coming up vehicle is important for the injury gravity only at greater or equal speed than 40 km/h [43].
- Examining the results of the paper [1], the teenage pedestrian head speed is greater than the teenage cyclist, since a part of the impact energy is dissipated by the bike chassis.

Following the ideas order in [38], the case of lateral impact can be examined to obtain the best value of some evaluation parameters.

Figure 19 and 20 show the trend of the head impact speed in the case of side impact versus the bumper height and the bonnet height respectively, for the several examined vehicle speeds. Of course three points for each speed are few to obtain an optimized result, so that a greater number of vehicles have to be examined to improve the result. One can note that the speed 40 and 50 km/h can be discarded since the result is influenced by the vehicle speed as paper [43] shows; the speed 20 km/h can be discarded since the speed is too low to arouse high injuries in the cyclist, so that the curve at speed 30 km/h can be manipulate to obtain the best values of the examined parameters.

No particular optimization procedure is applied in this case, but the three points are interpolated by a parabola; fig 21 and 22 show the relative curve.
Fig. 21 shows the best value of the bumper height corresponding to the minimum of the parabola and the minimum value of the head impact speed (9.88 m/s).

![Image](image1.png)

**Figure 22**- best value of the bonnet height.

Fig. 22 shows the best value of the bonnet height, corresponding at head impact speed equal to 9.81 m/s.

One can note that, in a suitable way, the same procedure should be applied to HIC values, nevertheless obtaining less satisfactory results. The values of the best values are a few different.

![Image](image2.png)

**Fig. 23 – best value of the bonnet angle**

Figure 23 shows the analogous determination for the bonnet angle; one can note that this value does the difference among the three examined vehicles, but the relative point of the Pick Up is inserted also if the head impact point is in a lower position than the bonnet height [43]. The head impact speed corresponding to the best value is 9.66 m/s.

The above procedure is executed for lateral crash only; its application to the other impact positions may give a few different results. Results obtained in this work cannot be considered definitive; best results can be obtained by increasing the number of examined vehicles, and also considering the other possible positions of impact. They may be used as the starting data for the mathematical procedures that can lead to improve the result.

5 Conclusions

In this work the impact performance with a teenager cyclist of three vehicles tested in previous works are compared. The lateral impact is chosen among the three different studied positions, following the suggestions of other determinations in literature. A literature research has allowed the identification of the following determinants geometric parameters of the frontal part of the vehicle: bumper height, bonnet height, bonnet angle, while the parameter used for the determination of the optimal values is the absolute speed of the head in the impact instant. The procedure for determining the optimal values cannot be defined as shape optimization, because the classical procedures cannot be applied for the skimpiness of available values. The obtained values are greatly enhanced in the conditions of a side impact teenage cyclist vehicle, even at different speeds from that of calculation. A similar procedure, not shown in the work, can be applied to the HIC values, obtaining small variations of the best values. The vehicles offering the best shape performance, among those examined, is the SUV, the speed of impact of the head is close enough to the minimum; in the determination with HIC, the representative point of this vehicle occupies a very close position to the minimum.

Next development of this work is the application of similar procedures for the chest, performing a compromise choice between the values obtained to minimize the injuries of the head and chest.
